# Docker Deep Dive, Part Two Container Runtimes

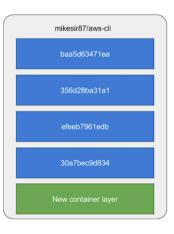

Michael Irwin - December 14, 2016

# What's a container again? How's it different than an image?

#### Containers are...

- Simply an image with its own writeable layer
- Remember that image layers are immutable. New changes go into the containers layer

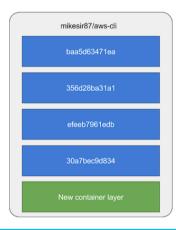

# Image layers are "unioned" together

- Each image layer is mounted read-only, with only the top layer mounted as writable
- Uses COW (Copy-On-Write) to keep things efficient
- Default implementation is AUFS, but work is being done to swap that to overlay2

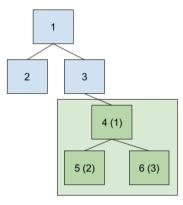

#### Uses the power of namespaces

- Provides kernel-level isolation of processes
- Was released in July 2008 with Linux 2.6.26
- Number of namespaces has increased over the years
- Think of it like chroot, but for other aspects of the operating system

# Process namespace isolation

- Breaks "traditional" view of a single process tree
- Introduces the ability to have "nested" process trees, with each tree being isolated
- Prevents processes in one tree from affecting (and even knowing about) processes in other trees

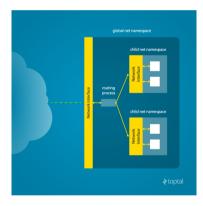

#### Container process isolation

- When a container is started, it gets its own process tree
- The default command is run as the root (PID 1)
- When PID 1 exits, the tree dies and the container is done

```
$ docker run --rm -ti ubuntu:16.04
root@a3c165bd5870:/# ps aux
USER
          PID %CPU %MEM
                          VSZ
                                RSS TTY
                                            STAT START
                                                         TIME COMMAND
            1 0.5 0.0 18240 3164 ?
                                            Ss
                                                 21:34
                                                         0:00 /bin/bash
root
           11 0.0 0.0 34424 2716 ?
                                                 21:34
root
                                                         0:00 ps aux
root@a3c165bd5870:/#
```

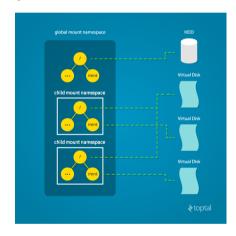

# Network namespace isolation

- Allows each process to see a completely different set of networking interfaces
  - Even the loopback interface is different for each namespace
- Each namespace gets virtual interfaces
- To make it work, a "routing process" has to route global network traffic to the correct interface

# Mount namespace

- Isolates metadata about mounted disk partitions, where they're mounted, what's read-only, etc.
- Gives the feel that each namespace has its own root

# User namespace

- Gives isolation of users and groups
- Allows users in one namespace to be completely isolated from another namespace
  - Reason why root in a container doesn't mean root on the host

# House vs Apartment

• Isolated vs Shared Infrastructure

#### Using cgroups

- Cgroups (Control Groups) provide resource controls
- Allows for soft and hard limits of CPU and RAM
- Does come with some overhead to keep up with the statistics
- Prevents one container from consuming all resources on the host, DOS'ing other containers
